Robotics

Robotics is an interdisciplinary field which integrates computer science, mechanical engineering, electrical engineering, information engineering, bioengineering, computer engineering, control engineering, software engineering, mathematics, etc.

The goal of robotics is to design machines that can assist humans or replicate human actions.
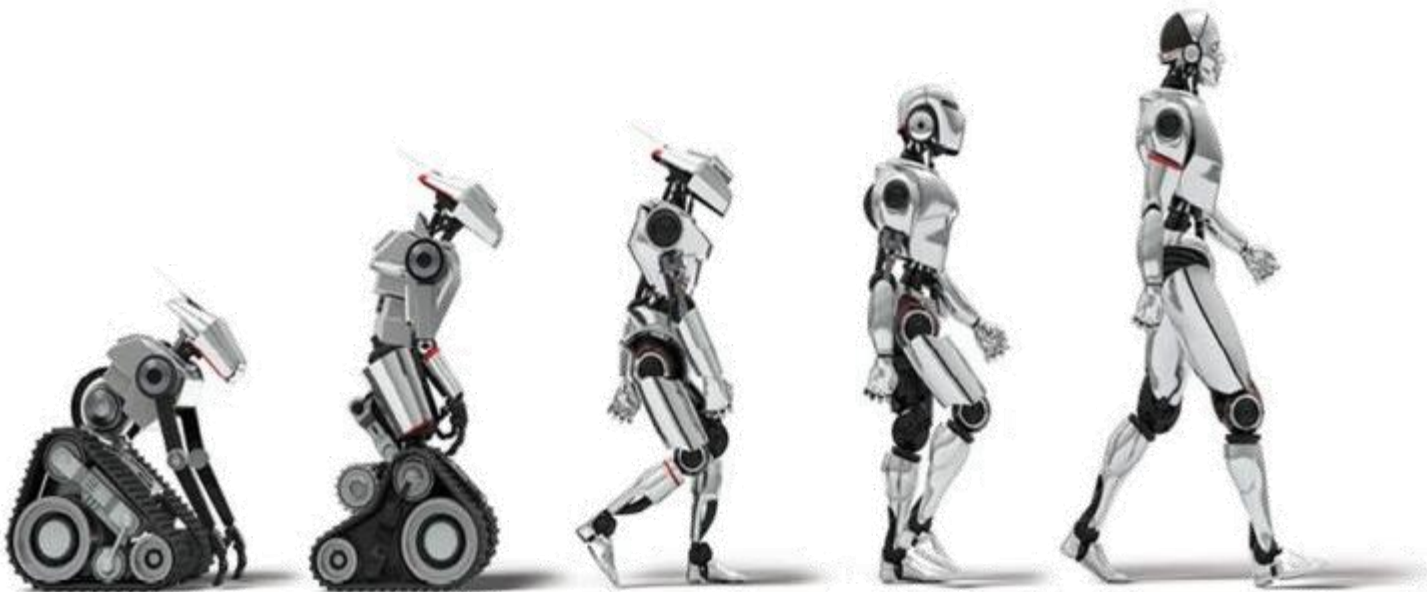

Robotics

- Classifications of robots based on structure:

- **Fixed-Base Robots** (e.g., <u>Serial or Open-Chain Manipulators</u>, Parallel Manipulators)
- **Mobile Robots**
    - **Ground Robots** (e.g., Wheeled Robots, Legged Robots)
    - **Submarine Robots**
    - **Aerial Robots**

Coordinate-Free Vector and Point

A **coordinate-free vector** v is a geometric quantity with a length and a direction.

Given a reference frame, vector v can be moved to a position such that the base of the arrow is at the origin without changing the orientation. Then, the vector v can be represented by its coordinates in the reference frame and denoted as $\boldsymbol{v}$.

- v refers to a physical quantity in the underlying space.
- $\boldsymbol{v}$ is a representation of v that <u>depends on the choice of coordinate frame</u>.

- A **point** p denotes a point in the physical space.
- A point p can be represented by as a **vector** from frame origin to p.
- $\boldsymbol{p}$ denotes the coordinate of a point p , which depends on the choice of reference frame.

Vector

$x \in \mathbb{R}^n$:   (an n-dimensional real vector in the column format)

$\mathbb{R}^n$: n-dimensional real space

Vector Norm

General Definition: Given $x \in \mathbb{R}^n$, vector norm $\|x\| \in \mathbb{R}_+$ is defined such that
- $\|x\| > 0$ when $x \neq \mathbf{0}$ and $\|x\| = 0$ iff $x = \mathbf{0}$.
- $\|kx\| = |k|\|x\|, \ \forall k \in \mathbb{R}$.
- $\|x + y\| \leq \|x\| + \|y\|, \ \forall y \in \mathbb{R}^n$.

❖ The p-norm (or ℓ_p-norm) of x for $p \in \mathbb{R}, p \geq 1$ is defined as $\|x\|_p := \left(\sum_{i=1}^{n} |x_i|^p \right)^{1/p}$

e.g. $\|x\|_2 = \|x\| = \sqrt{x^T x}$ (Euclidean Norm)

Special case: $\|x\|_\infty := \max_i |x_i|$

Schwartz Inequality: $|x^T y| \leq \|x\|_2 \|y\|_2 \quad \forall x, y \in \mathbb{R}^n$

Unit Vector: $\hat{x} = x/\|x\|_2, \quad \|\hat{x}\|_2 = \hat{x}^T \hat{x} = 1$

Dot Product or Scalar Product or Inner Product

Dot Product or Scalar Product or Inner Product of two vectors $x \in \mathbb{R}^n$, $y \in \mathbb{R}^n$ is a <u>scalar</u> defined as

(Algebraic Definition)
$$< x, y >= x \cdot y = \sum_{i=1}^{n} x_i y_i = x^T y = y^T x$$

(Geometric Definition)
$$< x, y >= x \cdot y = \|x\|_2 \|y\|_2 \cos \theta$$
$$(0 \leq \theta \leq \pi)$$

Cross Product or Vector Product

Cross product of $x, y \in \mathbb{R}^3$ (in the Euclidean space) is defined as a <u>vector</u> $v = x \times y \in \mathbb{R}^3$ that is orthogonal to both x and y ($v \perp x$, $v \perp y$), with a direction given by the right-hand rule and a magnitude equal to the area of the parallelogram that the vectors span.

$$\|v\|_2 = \|x\|_2 \|y\|_2 \sin\theta \quad (0 \le \theta \le \pi)$$
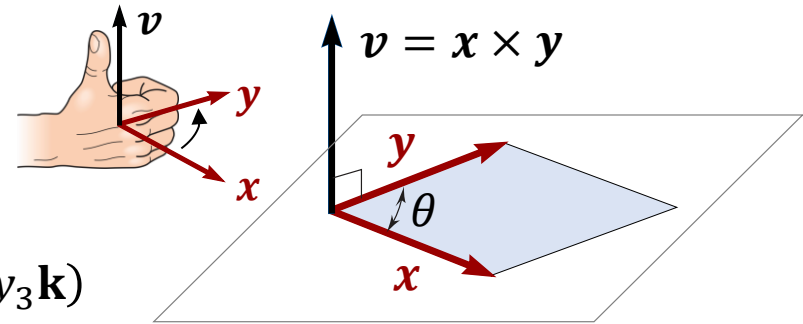

$$v = x \times y = (x_1\mathbf{i} + x_2\mathbf{j} + x_3\mathbf{k}) \times (y_1\mathbf{i} + y_2\mathbf{j} + y_3\mathbf{k})$$

Coordinate notation

$$x = (x_1, x_2, x_3), y = (y_1, y_2, y_3)$$

$$v = x \times y = \begin{vmatrix} \mathbf{i} & \mathbf{j} & \mathbf{k} \\ x_1 & x_2 & x_3 \\ y_1 & y_2 & y_3 \end{vmatrix}$$

Matrix notation

Gradient

For a **scalar function** $f \colon \mathbb{R}^n \to \mathbb{R}$ which is differentiable with respect to the elements x_i of $\boldsymbol{x} \in \mathbb{R}^n$, its **gradient** with respect to $\boldsymbol{x}$ is an n-dimensional column vector $\boldsymbol{\nabla}_{\boldsymbol{x}} f \in \mathbb{R}^n$ as:

(nabla symbol and pronounced "del")

$$\boldsymbol{\nabla}_{\boldsymbol{x}} f(\boldsymbol{x}) = \left(\frac{\partial f}{\partial \boldsymbol{x}}\right)^T = \begin{bmatrix} \dfrac{\partial f(\boldsymbol{x})}{\partial x_1} \\ \vdots \\ \dfrac{\partial f(\boldsymbol{x})}{\partial x_n} \end{bmatrix}$$

$$f(x_1, x_2) = -(\cos^2 x_1 + \cos^2 x_2)^2$$
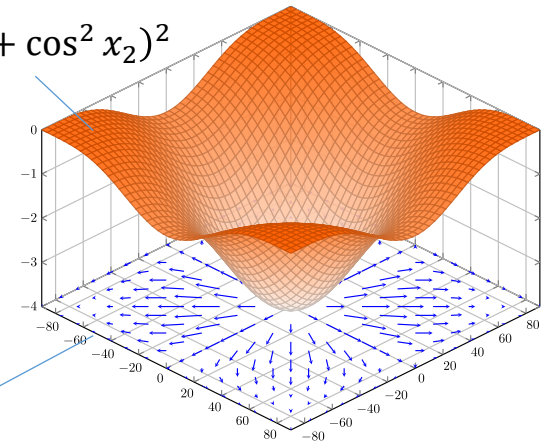

The gradient depicted as a projected vector field and shows the direction and rate at which a function increases the fastest at a given point.

- If $\boldsymbol{x}(t)$ is a differentiable function with respect to t:

$$\dot{f}(\boldsymbol{x}) = \frac{d}{dt} f(\boldsymbol{x}(t)) = \frac{\partial f}{\partial \boldsymbol{x}} \frac{d\boldsymbol{x}}{dt} = \frac{\partial f}{\partial \boldsymbol{x}} \dot{\boldsymbol{x}} = \boldsymbol{\nabla}_{\boldsymbol{x}}^T f(\boldsymbol{x}) \dot{\boldsymbol{x}} \qquad \text{(Chain Rule)}$$

Cross Product as a Matrix-Vector Multiplication

Cross product $x \times y$ ($x, y \in \mathbb{R}^3$) can be thought of as a multiplication of a vector by a 3×3 skew-symmetric matrix as

$$x \times y = \underbrace{\begin{bmatrix} 0 & -x_3 & x_2 \\ x_3 & 0 & -x_1 \\ -x_2 & x_1 & 0 \end{bmatrix}}_{[x]} \begin{bmatrix} y_1 \\ y_2 \\ y_3 \end{bmatrix} = [x]y$$

$$x = (x_1, x_2, x_3),$$
$$y = (y_1, y_2, y_3)$$

The matrix $[x] \in \mathbb{R}^{3 \times 3}$ is a <u>skew-symmetric matrix representation</u> of x. $[x] = -[x]^T$

- $[x]y = -[y]x$

Jacobian

For a **vector function** $\boldsymbol{f}: \mathbb{R}^n \to \mathbb{R}^m$ whose elements f_i are differentiable with respect to the elements x_i of $\boldsymbol{x} \in \mathbb{R}^n$, its **Jacobian** with respect to $\boldsymbol{x}$ is matrix $\boldsymbol{J_f} \in \mathbb{R}^{m \times n}$ as:

$$\boldsymbol{J_f}(\boldsymbol{x}) = \frac{\partial \boldsymbol{f}(\boldsymbol{x})}{\partial \boldsymbol{x}} = \begin{bmatrix} \dfrac{\partial f_1(\boldsymbol{x})}{\partial \boldsymbol{x}} \\ \dfrac{\partial f_2(\boldsymbol{x})}{\partial \boldsymbol{x}} \\ \vdots \\ \dfrac{\partial f_m(\boldsymbol{x})}{\partial \boldsymbol{x}} \end{bmatrix}$$

- If $\boldsymbol{x}(t)$ is a differentiable function with respect to t:

$$\dot{\boldsymbol{f}}(\boldsymbol{x}) = \frac{d}{dt} \boldsymbol{f}\big(\boldsymbol{x}(t)\big) = \frac{\partial \boldsymbol{f}}{\partial \boldsymbol{x}} \frac{d\boldsymbol{x}}{dt} = \frac{\partial \boldsymbol{f}}{\partial \boldsymbol{x}} \dot{\boldsymbol{x}} = \boldsymbol{J_f}(\boldsymbol{x}) \dot{\boldsymbol{x}} \qquad \text{(Chain Rule)}$$

Range/Column Space, Null Space, and Row Space

- The **linear transformation** (or linear map) between the vectors $x \in \mathbb{R}^n$ and $y \in \mathbb{R}^m$ can be defined as

$$y = Ax \qquad\qquad A \in \mathbb{R}^{m \times n}$$

- The **range space** or **column space** (or **range** or **image**) of the transformation/matrix A is the subspace generated by the <u>linearly independent columns</u> of matrix A.

$$\mathcal{R}(A) = \mathcal{C}(A) = \{y : y = Ax, x \in \mathbb{R}^n\} \subseteq \mathbb{R}^m$$

Note: $\dim \mathcal{R}(A) = \mathrm{rank}(A)$

- The **null space** (or **null**) of the transformation/matrix A is the subspace
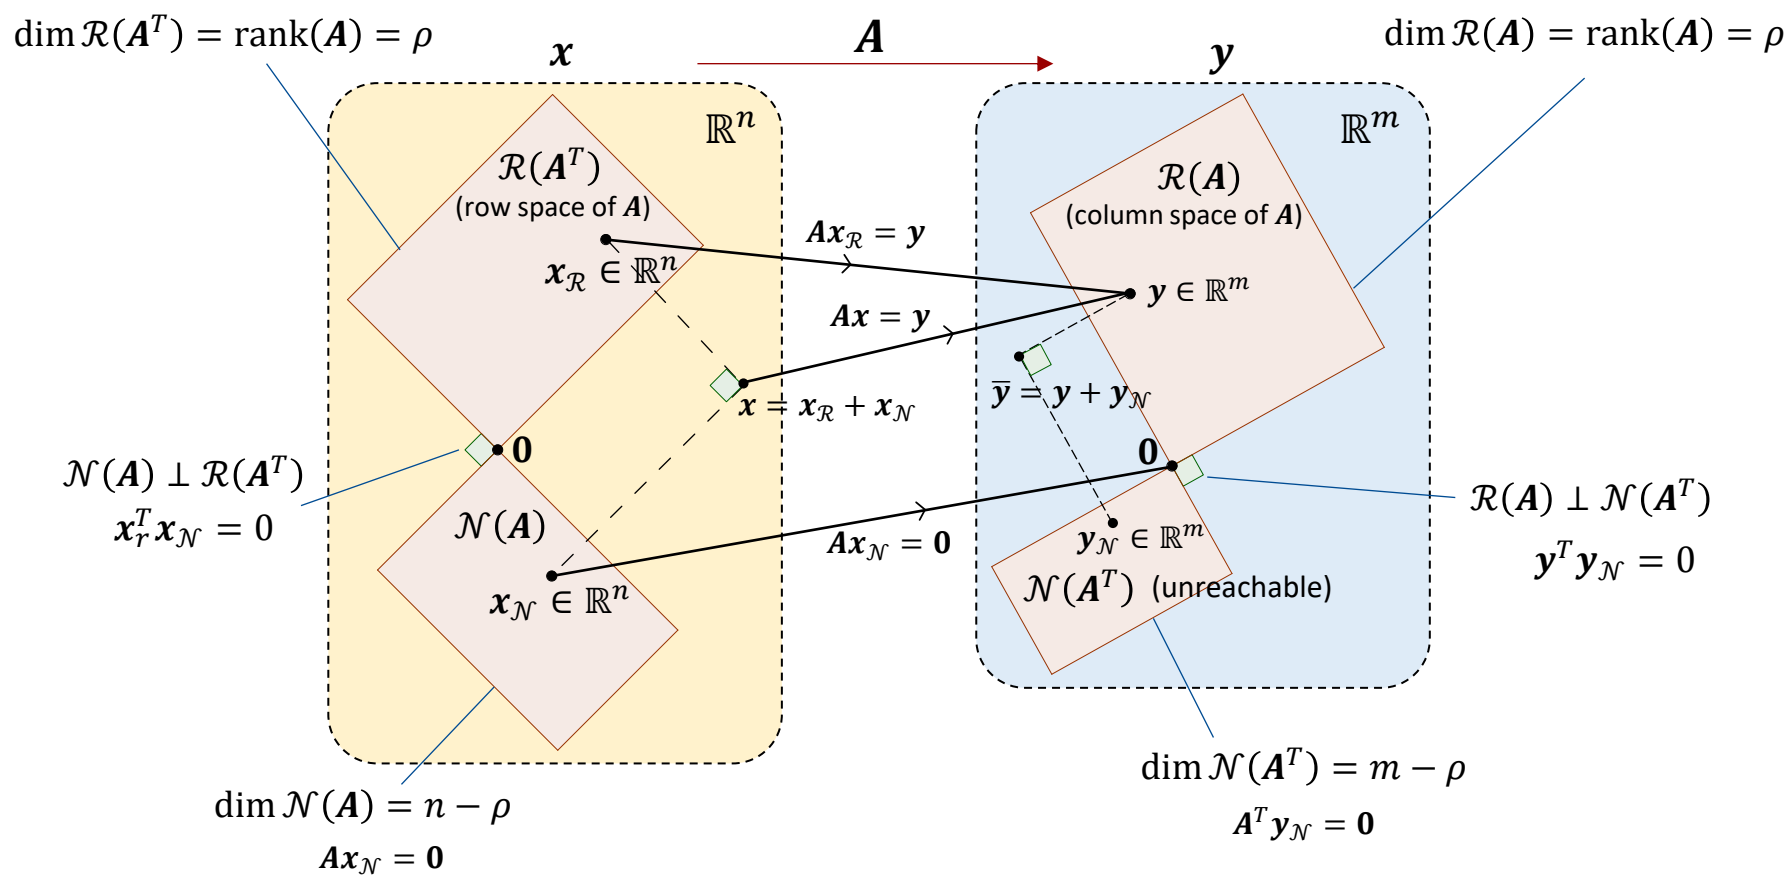

$$\mathcal{N}(A) = \{x : Ax = 0, x \in \mathbb{R}^n\} \subseteq \mathbb{R}^n$$

Note: $\dim \mathcal{R}(A) + \dim \mathcal{N}(A) = n$

Therefore, if $\mathrm{rank}(A) = \rho \leq \min\{m, n\}$, then $\dim \mathcal{R}(A) = \rho$ and $\dim \mathcal{N}(A) = n - \rho$.

- The **row space** of A is the same as the range/column space of A^T, i.e., $\mathcal{R}(A^T)$.

Stony Brook University

Pseudo-Inverse

The inverse of a matrix A can be defined as A^{-1} only when the matrix is square and nonsingular (full rank). However, the inverse operation can be extended to the case of non-square (and singular) matrices as **Pseudo-Inverse** or **Moore–Penrose Inverse** A^+.

For $A \in \mathbb{R}^{m \times n}$, a pseudoinverse is defined as a matrix $A^+ \in \mathbb{R}^{n \times m}$ satisfying all of the following four criteria (Moore–Penrose conditions):

- $AA^+A = A$
- $A^+AA^+ = A^+$
- $(AA^+)^T = AA^+$
- $(A^+A)^T = A^+A$

Note: The pseudoinverse A^+ exists for <u>any matrix</u> A.

❖ If $A \in \mathbb{R}^{m \times n}$ is not full rank, i.e., $\text{rank}(A) < \min\{m, n\}$, a computationally simple and accurate way to compute pseudoinverse A^+ is by using the **Singular Value Decomposition**.

❖ If $A \in \mathbb{R}^{m \times n}$ is full rank, i.e., $\text{rank}(A) = \min\{m, n\}$, then $A^+ \in \mathbb{R}^{n \times m}$ can be given a particularly simple algebraic expression (see Special Cases in the next slides).

○○	○○○○○○○○	○○○○○○	○○○○	○●○○	○○○	○○○○○○

Stony Brook University

Special Case 1: Right Pseudo-Inverse

- If $m < n$ (fat matrix) and $\text{rank}(A) = m$ (equivalently, A has linearly independent rows and AA^T is invertible):

$$A^+ = A^T(AA^T)^{-1} \qquad \text{(right pseudo-inverse as } AA^+ = I_m)$$

Weighted Right Pseudo-inverse:

If $W_r \in \mathbb{R}^{n \times n}$ is a positive definite matrix[1], a weighted right pseudo-inverse is given by

$$A^+ = W_r^{-1}A^T(AW_r^{-1}A^T)^{-1}$$

---

[1] A square not necessarily symmetric matrix $A \in \mathbb{R}^{n \times n}$ is Positive Definite (PD or $A > 0$) if $x^T A x > 0$ for all nonzero $x \in \mathbb{R}^n$.

Stony Brook University

Special Case 2: Left Pseudo-Inverse

- If $m > n$ (tall matrix) and $\text{rank}(A) = n$ (equivalently, A has linearly independent columns and $A^T A$ is invertible):

$$A^+ = (A^T A)^{-1} A^T \qquad \text{(left pseudo-inverse as } A^+ A = I_n)$$

Weighted Left Pseudo-inverse:

If $W_l \in \mathbb{R}^{m \times m}$ is a positive definite matrix, a weighted right pseudo-inverse is given by

$$A^+ = (A^T W_l A)^{-1} A^T W_l$$

Remarks

- If A is a square full-rank matrix, then $A^+ = A^{-1}$.
- A^+A projects any vector onto the row space of A or column space of A^T, i.e., $\mathcal{R}(A^T)$.
- $I_n - A^+A$ projects any vector onto the null space of A, i.e., $\mathcal{N}(A)$.
- AA^+ projects any vector onto the column space of A, i.e., $\mathcal{R}(A)$.
- $I_m - AA^+$ projects any vector onto the null space of A^T, i.e., $\mathcal{N}(A^T)$.
- The pseudo-inverse is very useful to invert a linear transformation $y = Ax$.

Eigenvalues and Eigenvectors

If the vector resulting from the linear transformation $A \in \mathbb{R}^{n \times n}$ on a vector u has the same direction of u (with $u \neq 0$), then $Au = \lambda u$.

For each square matrix $A \in \mathbb{R}^{n \times n}$ there exist n **eigenvalues** (in general, complex numbers) denoted by $\lambda_i(A)$, $i = 1, \ldots, n$ that satisfy

$$\text{(characteristic equation)} \quad \det(A - \lambda_i(A)I) = 0 \qquad I = \text{diag}(1) \in \mathbb{R}^{n \times n}$$

- If $A = A^T$, then $\lambda_i(A) \in \mathbb{R}$ ($i = 1, \ldots, n$) and its eigenvectors are always orthogonal, regardless of whether A is full rank or not.

Eigenvectors u_i associated with the eigenvalues λ_i satisfy $(A - \lambda_i I)u_i = 0 \qquad i = 1, \ldots, n$

- If the eigenvectors u_i of A are linearly independent, matrix U formed by the column vectors u_i is invertible and $\Lambda = U^{-1}AU$ where $\Lambda = \text{diag}(\lambda_1, \ldots, \lambda_n)$. If A is symmetric, U is orthogonal ($UU^T = U^T U = I$) and $\Lambda = U^T AU$.

  $\Rightarrow$ Eigendecomposition: $A = U\Lambda U^{-1}$ and if A is symmetric $A = U\Lambda U^T$.

- $\det(A) = \prod_{i=1}^{n} \lambda_i$
- $\lambda(A^T) = \lambda(A)$
- $\lambda(A^{-1}) = 1/\lambda(A)$

Singular Values and Condition Number

For a nonsquare matrix it is not possible to define eigenvalues and eigenvectors. An extension of the eigenvalue concept can be obtained by **Singular Values**.

For $A \in \mathbb{R}^{m \times n}$, matrices $AA^T \in \mathbb{R}^{m \times m}$ and $A^T A \in \mathbb{R}^{n \times n}$ are symmetric and positive semi-definite (PSD), and, therefore, have (m for AA^T and n for $A^T A$) real and nonnegative eigenvalues. Moreover, they have always the same <u>non-zero eigenvalues</u>. The **Singular Values** for matrix A are given by the square roots of the eigenvalues of AA^T (if $m < n$) or $A^T A$ (if $n < m$):

$$\sigma_i = \sqrt{\lambda_i}, \qquad i = 1, \dots, \min(m, n)$$

Notes:

- The number of singular values σ_i is always $\min(m, n)$ and the number of non-zero singular values σ_i is equal to $\rho = \mathrm{rank}(A)$ ($\sigma_1 \geq \cdots \geq \sigma_\rho > 0$).
- According to a geometric interpretation, the matrix A transforms the unit sphere in $\mathbb{R}^n$ defined by $\|x\| = 1$ into the set of vectors $y = Ax$ which define an ellipsoid of dimension $\rho = \mathrm{rank}(A)$ in $\mathbb{R}^m$. The singular values σ_i are the lengths of the various axes of the ellipsoid.
- The **Condition Number** of matrix A is defined as $\kappa = \sigma_1 / \sigma_\rho$ (the eccentricity of the ellipsoid).

Singular Value Decomposition (SVD)

The **Singular Value Decomposition** (**SVD**) of the matrix A is then given by $\quad A = U\Sigma V^T$

- $U = [u_1, u_2, \ldots, u_m] \in \mathbb{R}^{m \times m}$ is an orthogonal matrix ($UU^T = U^TU = I_m$) that u_i (called left singular vectors) are eigenvectors of AA^T ($AA^Tu_i = \lambda_i u_i = \sigma_i^2 u_i$).
- $V = [v_1, v_2, \ldots, v_n] \in \mathbb{R}^{n \times n}$ is an orthogonal matrix ($VV^T = V^TV = I_n$) that v_i (called right singular vectors) are eigenvectors of A^TA ($A^TAv_i = \lambda_i v_i = \sigma_i^2 v_i$).
- $\Sigma = \begin{bmatrix} D & 0 \\ 0 & 0 \end{bmatrix} \in \mathbb{R}^{m \times n}$ is a matrix where $D = \text{diag}\{\sigma_1, \sigma_2, \ldots, \sigma_r\}$ and $\sigma_1 \geq \cdots \geq \sigma_\rho > 0$.

❖ SVD is used to compute the (right or left) **pseudoinverse** A^+, even if A is not full rank.

$$A^+ = V\Sigma^+ U^T$$

$$\Sigma^+ = \begin{bmatrix} D^+ & 0 \\ 0 & 0 \end{bmatrix}, \qquad D^+ = \text{diag}\left\{\frac{1}{\sigma_1}, \frac{1}{\sigma_2}, \ldots, \frac{1}{\sigma_r}\right\}$$

Solving $Ax = y$

Consider $Ax = y$ (where $A \in \mathbb{R}^{m \times n}$ and $y \in \mathbb{R}^m$ are <u>given</u> and $x \in \mathbb{R}^n$ is <u>unknown</u>).

❖ If A is invertible, i.e., square and full rank, $\mathrm{rank}(A) = n = m$, there is a unique solution x as $x = A^{-1}y$.

❖ If A is not invertible, i.e., A is not square ($n \neq m$) but full rank or rank deficient ($\mathrm{rank}(A) < \min(m, n)$, square or nonsquare), $Ax = y$ can still be solved (or approximately solved) for x with the Moore–Penrose pseudoinverse A^+ as $x^* = A^+y$ which minimizes the norm $\|Ax - y\|_2$.

❖ Exact solution(s) exist if and only if $y \in \mathcal{R}(A)$ or $AA^+y = y$, otherwise, the solution will be approximate with minimum error.

Solving $Ax = y$
(Case 1)

- If $m < n$ (fat matrix) and $A \in \mathbb{R}^{m \times n}$ is full (row) rank, i.e., $\text{rank}(A) = m$ or $\mathcal{N}(A^T) = \emptyset$ (this satisfies the solution existence condition $y \in \mathcal{R}(A)$), <u>infinite exact solutions</u> exist. The solutions are in the form

$$x = \underbrace{x^*}_{\text{particular solution}} + \underbrace{Px_0}_{\text{homogeneous solution}} = A^+ y + (I_n - A^+ A)x_0 \quad \text{for arbitrary vector } x_0 \in \mathbb{R}^n \quad (1)$$

  where $A^+ = A^T(AA^T)^{-1}$ and it is the right pseudo-inverse as $AA^+ = I_m$.

- The solution (1) is derived from this constrained linear optimization problem:

$$\min_{x} \quad \frac{1}{2}(x - x_0)^T(x - x_0)$$
$$\text{subject to} \quad Ax = y$$

- Among all these solutions, $x^* = A^+ y \in \mathcal{R}(A^T)$ minimizes $\|x\|_2$ (you can see this by setting $x_0 = 0$ is the above optimization problem).
- Matrix $P = (I_n - A^+ A) \in \mathbb{R}^{n \times n}$ is null-space projection matrix where $\mathcal{R}(P) = \mathcal{N}(A)$.
- The term $x_{\mathcal{N}} = (I_n - A^+ A)x_0$ is the projection of x_0 in $\mathcal{N}(A)$ where $Ax_{\mathcal{N}} = 0$.
- We can also use the weighted right pseudo-inverse as $A^+ = W_r^{-1} A^T (A W_r^{-1} A^T)^{-1}$. $W_r \in \mathbb{R}^{n \times n}$ is a positive definite matrix.

Solving $Ax = y$
(Case 2)

- If $m > n$ (tall matrix) and $A \in \mathbb{R}^{m \times n}$ is full (column) rank, i.e., $\mathrm{rank}(A) = n$ or $\mathcal{N}(A) = \emptyset$, when $y \in \mathcal{R}(A)$, <u>a unique exact solution</u> exists, and when $y \notin \mathcal{R}(A)$, <u>no exact solutions</u> but <u>an approximate solutions</u> exist. In both cases, the solutions are in the form

$$x = A^+ y \qquad (1)$$

  where $A^+ = \left(A^{\mathrm{T}} A\right)^{-1} A^{\mathrm{T}}$ and it is the left pseudo-inverse as $A^+ A = I_n$.

  - If $y \in \mathcal{R}(A)$ or $AA^+ y = y$, then $x = A^+ y$ gives the unique exact solution.
  - If $y \notin \mathcal{R}(A)$ or $AA^+ y \neq y$, then $x = A^+ y$ minimizes the norm of the error $\|Ax - y\|_2$ and gives an approximate solution x^*.

- The solution (1) is derived from this optimization problem: $\quad \min_x \dfrac{1}{2}(Ax - y)^T (Ax - y)$

- We can also use the weighted left pseudo-inverse as $A^+ = (A^T W_l A)^{-1} A^T W_l$. $W_l \in \mathbb{R}^{m \times m}$ is a positive definite matrix.

Stony Brook University

Solving $Ax = y$
(Case 3: General Case) - (Method 1)

- If $A \in \mathbb{R}^{m \times n}$ (square or non-square) is rank deficient (i.e., $\text{rank}(A) < \min(m, n)$, $\mathcal{N}(A) \neq \emptyset$, and $\mathcal{N}(A^{\text{T}}) \neq \emptyset$), when $y \in \mathcal{R}(A)$, <u>infinite exact solutions</u> exist, and when $y \notin \mathcal{R}(A)$, <u>no exact solutions</u> but <u>infinite approximate</u> solutions exist. In both cases, the solutions are in the form

$$x = A^+ y + (I_n - A^+ A)x_0 \quad \text{for arbitrary vector } x_0 \in \mathbb{R}^n$$

and A^+ is pseudo-inverse which is computed using the **Singular Value Decomposition (SVD)**.

- If $y \in \mathcal{R}(A)$ or $AA^+ y = y$, exact solution $A^+ y$ minimizes $\|x\|_2$ and $(I_n - A^+ A)x_0$ represents all vectors in $\mathcal{N}(A)$.
- If $y \notin \mathcal{R}(A)$ or $AA^+ y \neq y$, approximate solution $A^+ y$ minimizes both $\|Ax - y\|_2$ and $\|x\|_2$ while all solutions $A^+ y + (I_n - A^+ A)x_0$ minimize only $\|Ax - y\|_2$.

Stony Brook University

Solving $Ax = y$
(Case 3: General Case) - (Method 2)

The **Damped Least Squares (DLS)** can be used to compute an <u>approximate</u> inverse or pseudoinverse of $A \in \mathbb{R}^{m \times n}$, especially when A is <u>singular or near-singular</u>:

$$A_D^+ \approx (A^T A + \lambda I_n)^{-1} A^T \quad \text{(right inverse)} \qquad (1)$$

$$A_D^+ \approx A^T (A A^T + \lambda I_m)^{-1} \quad \text{(left inverse)} \qquad (2)$$

$\lambda \in \mathbb{R}_+$ is the **damping (regularization) parameter** which introduces a trade-off between accuracy of the solution and numerical stability. A larger λ improves stability for very ill-conditioned matrices but may reduce accuracy (i.e., away from true least squares solution). In general, choosing the optimal damping factor λ can be challenging.

- These forms are mathematically equivalent. For computational efficiency, use (1) when $n \leq m$ and use (2) when $m \leq n$ (which relates to which matrix $A^T A$ or $A A^T$ is smaller).
- The addition of λI_n or λI_m ensures that the matrix is invertible even when $A^T A$ or $A A^T$ are singular or nearly singular.

Solving $Ax = y$
(Case 3: General Case) - (Method 2)

Using Damped Least Squares (DLS), we can find <u>approximate solutions</u> x to $Ax = y$ in the form

$$x \approx A_D^+ y + (I_n - A_D^+ A)x_0 \quad \text{for arbitrary vector } x_0 \in \mathbb{R}^n \qquad (1)$$

The approximate particular solution $A_D^+ y$ minimizes $\|Ax - y\|_2 + \lambda\|x\|_2$ and the approximate homogeneous solution $(I_n - A^+ A)x_0$ represents all vectors in $\mathcal{N}(A)$.

- The solution (1) is derived from this optimization problem:

$$\min_{x} \quad \frac{1}{2}(Ax - y)^T(Ax - y) + \frac{1}{2}\lambda \dot{x}^T \dot{x}$$

DLS Method vs SVD Method:
- DLS is simpler and computationally less expensive, making it ideal for real-time applications like robotics requiring quick, stable solutions, but the solutions are approximate, and it introduces a uniform bias.
- SVD provides a more comprehensive and flexible approach, providing a complete picture of the matrix's properties and allowing for selective treatment of singular values, leading to potentially more accurate solutions, but at the cost of higher computational effort. Moreover, SVD is more sensitive to small changes in the matrix and to ill-conditioning.
